FLOOD-VOLUME DESIGN DATA FOR MISSOURI STREAMS

By John Skelton

ABSTRACT

Results of a statistical analysis of flood-volume information for Missouri are presented in this report. Flood-volume-duration data for selected recurrance intervals are tabulated for 111 continuous-record gaging stations.

By regression analysis, regional flood-volume equations applicable to ungaged sites with drainage basins as small as 0.2 square mile were defined for the Plains and Plateaus regions. Four basin characteristics (drainage area, mean basin elevation, mean runoff, and soils infiltration index) were found to be statistically significant in defining flood volumes; one or more of these variables is required in computing the equations.

INTRODUCTION

During recent years the nationwide construction of flood-control reservoirs and the allocation of capacity in multi-purpose reservoirs for flood control have increased at a higher rate than for any other uses. Growth in numbers and capacity of small flood-storage projects and an increasing use of flood-volume data in design problems appear to be continuing.

Past storage analyses (Skelton, 1968 and 1971) have furnished data that are useful in the design of reservoirs to insure dependable year-round water supplies in Missouri. However, for the planning, design, construction and operation of projects that include the storage of flood waters, flood-volume data are needed. These data can be used to determine the quantity of water to be stored in order to reduce flood damage downstream, for computing waterway capacity for highway drainage structures and for designing spillways for dams.

Discussions with personnel of state and federal agencies and engineering consulting firms during early phases of this project indicated that the information

most helpful to them in their work with floodstorage problems would be (1) flood-volume design data at gaged sites and (2) a method of estimating design volumes at ungaged sites, especially for small drainage areas. Consequently, this report is tailored to meet the needs expressed by the primary users of flood-volume data. It contains a tabulation of floodvolume-duration data for selected recurrence intervals at continuous-record stations in the state and presents regional equations for estimating these data at ungaged sites with drainage basins as small as 0.2 square mile.

This report was prepared in the Missouri district of the U.S. Geological Survey, under the direction of Anthony Homyk, District Chief, in cooperation with the Missouri Geological Survey and Water Resources, Wallace B. Howe, State Geologist and Director. The information in this report is based on data collected by the U.S. Geological Survey in cooperation with state and federal agencies.

PHYSIOGRAPHY

Past hydrologic studies in Missouri have shown that physiography has a very pronounced effect on streamflow characteristics. Thus it is important to define the distinctive physiographic regions of the state as a prelude to describing the flood-volume analysis.

The three physiographic divisions of Missouri are the Plains (Osage Plains and Dissected Till Plains), Ozarks (Plateaus) and Southeastern Lowlands (fig. 1).

The Plains is primarily a region of wide valleys with rolling hills. Elevations range from 450 feet above sea level near the Mississippi River to 1,000 feet in the western parts of the area. Much of the region is covered by weathered drift brought in by Ice Age glaciers, causing relatively homogeneous hydrologic conditions throughout the area. As a result, flood-runoff prediction is more accurate for this region than for any other in the state.

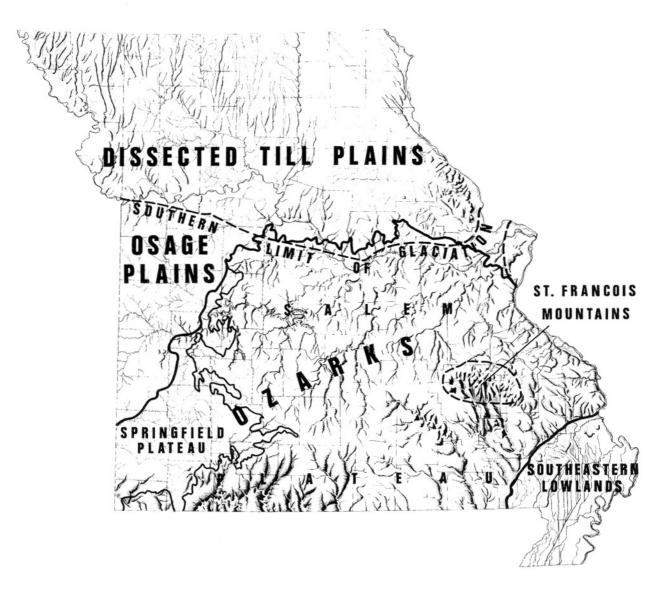

Figure 1

Map of the physiographic divisions of Missouri

The Ozarks region is a fairly rugged area of deep, narrow valleys and sharp ridges in the Salem Plateau area. The Springfield Plateau is generally characterized by rolling hills and wider stream valleys. Elevations in the Ozarks range from about 1,000 feet above sea level to more than 1,600 feet. In some stream basins of the area, intense solutional development in the carbonate rocks, faulting and jointing cause non-homogeneous flood-runoff patterns by diverting major portions of the flood runoff to underground storage. Thus, generalization of streamflow characteristics is difficult, requiring delineation of these anomalous losing areas whenever possible.

The Southeastern Lowlands region, which is located on the Mississippi River alluvial plain, is a relatively flat area of excellent farmland that is drained by numerous man-made channels. Elevations range from 230 to 300 feet above sea level with the exception of Crowley's Ridge where elevations are about 500 feet. Adequate regionalization of hydrologic data in this region is virtually impossible because of difficulty in measuring basin characteristics such as contributing drainage area (it often changes with stream stage) and the uncertainty associated with numerous and frequent man-made changes.

GENERALIZED DESCRIPTION OF FLOOD-RUNOFF PATTERNS

The following brief description of flood-runoff patterns in Missouri is taken from Skelton and Homyk (1970):

"Almost all areas of the State are subject to occasional flooding. Flood runoff per square mile is generally greater in the Ozarks Plateaus than in other areas of the State for drainage areas of comparable size, primarily because of the more rugged topography. However, runoff is quite variable in some sections of the Plateaus during low-order floods because of structural and karst effects. Fault zones and extensive areas of solution openings (sinkholes)

in a basin can transmit large quantities of flood runoff from the surface to underground storage reservoirs, causing anomalous patterns of flood runoff. In general, these effects are not evident for floods with recurrence intervals greater than 5 years, although there are some notable exceptions to this rule.

In an average year floods in Missouri are more likely to occur in June, with March and April in second and third place, respectively. Floods are least likely to occur from November through January."

FLOOD-VOLUME-FREQUENCY CHARACTERISTICS AT GAGING STATIONS

The network of gaging stations used to provide data for the flood-volume analysis is shown in plate 1. The stations shown are those that met the following criteria:

- Ten or more years of available daily-discharge records.
- b. More than 25-percent difference in drainage area between gaging stations located on the same stream.
- c. Flood data not materially affected by regulation.
- d. Adequate definition of the stage-discharge relation.

Annual highest mean discharges in cfs (cubic feet per second) for selected periods were determined from these records by computer. A sample of this output, which is available for 111 Missouri gaging stations, is shown in table 1.

TABLE 1

Annual highest mean discharges, in cubic feet per second, for
Thompson Branch near Albany, Mo. (Drainage area = 5.58 square miles)

YEAR	1 Day	3 Days	7 Days	15 Days	30 Days
1956	41.0	21.8	9.3	4.4	2.2
1957	27.0	10.3	4.4	2.1	1,1
1958	290.0	105.0	81.8	44.8	25.9
1959	312.0	114.0	68.5	32.3	16.1
1960	210.0	156.0	78.9	38.3	22.7
1961	400.0	157.0	69.4	51.7	27.0
1962	121.0	83.1	41.7	25.0	16.4
1963	33.0	21.7	10.4	7.0	4.0
1964	220.0	123.0	55.3	26.3	13.3
1965	182.0	132.0	70.0	35.1	18.8
1966	25.0	11.8	6.2	3.0	1.7
1967	125.0	72.3	34.0	25.1	15.6
1968	32.0	13.0	5.6	3.5	1.8
1969	264.0	163.0	71.2	35.3	23.2
1970	197.0	80.3	36.3	23.7	14.5

For the convenience of those using these data, the highest mean discharges are converted to acre-feet for presentation in the appendix. These data represent the annual highest flood volumes for 1-, 3-, 7-, 15and 30-day periods for selected recurrence intervals at all gaging stations plus 6-, 12- and 18-hour manually-tabulated data for stations with drainage areas less than 50 square miles. The characteristics are noted symbolically in the text and tables. For example, V.25.2 represents a 6-hour flood volume with recurrence interval of 2 years; V7,25 represents a 7-day flood volume with recurrence interval of 25 years. The 1- to 30-day frequency data for all stations were determined by computer, mathematically fitting a Pearson Type III distribution to the logarithms of the annual flood-volume data, as described by the Water Resources Council (1967). Figure 2 is an example of the log-Pearson Type III curve of annual highest mean discharges for a Missouri gaging station. A graphical frequency curve is used for

those stations for which the log-Pearson Type III curve is not a reasonable fit to the data.

Small-area streams in Missouri generally have highly variable flows. Figures of highest mean discharge for durations of less than one day are needed because a large percentage of the total flood volume may occur in short periods on these streams. For the 6-, 12- and 18-hour periods shown in the appendix, a combination of manual tabulation and graphical procedures were used to compute the necessary frequency data. The highest mean discharge for a period of 24 hours is nearly always greater than that of a calendar day during any given year on these streams. Therefore, manually-tabulated 24-hour data were used in the computations instead of 1-day data furnished by the computer for small-area stations, and graphical adjustments to 3-day data were made where necessary for greater accuracy. All small-area frequency computations were based on the adjusted data.

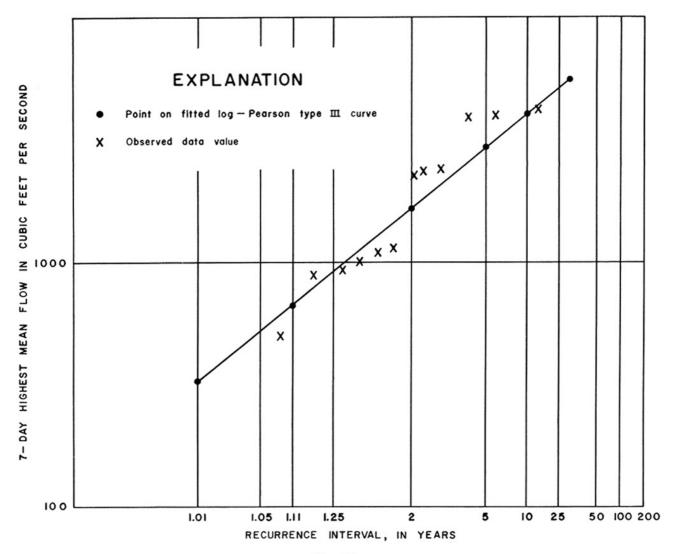

Figure 2
Frequency curve of 7-day highest mean discharges of James River near Springfield, Mo.

TRANSFER OF INFORMATION TO UNGAGED SITES

Each of the flood-volume characteristics defined at gaging stations were related to basin and climatic characteristics by regression; the resulting equations may be used to estimate flood-volume characteristics at ungaged sites.

such as 1-day flood volume with recurrence interval of 2 years $(V_{1,2})$; the X's are topographic or climatic characteristics; and the other symbols are coefficients obtained by regression.

The regression model used is: $\log Y = \log a + b_1 \log X_1 + b_2 \log X_2 - \cdots - b_n \log X_n$, where Y is a statistical flood-volume characteristic

Several graphical plots, made early in this study, established the general applicability of this model to the variables used in the analysis.

In the initial phases of this study, the following independent variables were included in the data matrix: drainage area (A), slope (S), length (L), surface storage (St), mean-basin elevation (E), forest cover (F), mean-annual precipitation (P), 2-year, 24-hour precipitation (T_{24,2}), mean-annual runoff (R), soils index (Si) and average basin width (W).

A prime assumption in regression analysis is that the various independent variables are not to be highly related to each other. To test this assumption for the flood-volume data matrix, a simple correlation matrix of the 11 evaluated basin characteristics was obtained and analyzed. This procedure indicated that the best results would be obtained by omitting two of

¹Equations are defined by data from streams with drainage areas of 2.5 to 14,000 square miles. Data from 53 gaging stations were used to compute the equations.

²Standard error is defined as the standard deviation of the distribution (assumed normal) of residuals about the regression line and is a measure of the reliability of a regression. A standard error of 30 percent, for example, indicates that the flood-volume estimate obtained from the equation will be within [±] 30 percent of the correct value at about two-thirds of the ungaged sites.

the variables, length and average basin width, from the data matrix, and this was done for the final regression runs.

The regression equations, standard errors of estimate and the statistical significance of the regression coefficients were obtained by digital computer using the nine basin characteristics chosen for the final analysis. The calculations were then repeated automatically with the least effective basin parameter being omitted in each calculation until only the most effective parameter remained. This procedure was repeated for all the flood volumes selected for this study. The equations selected for use have relatively low standard errors and include only those independent variables that are statistically significant at the 99-percent level.

¹ Equations are defined by data from streams with drainage areas of 0.2 to 3,800 square miles. Data from 55 gaging stations were used to compute the equations.

²Standard error is defined as the standard deviation of the distribution (assumed normal) of residuals about the regression line and is a measure of the reliability of a regression. A standard error of 30 percent, for example, indicates that the flood-volume estimate obtained from the equation will be within ± 30 percent of the correct value at about two-thirds of the ungaged sites.

The independent variables included in the equations of tables 2, 3, and 4 are defined as follows:

- a. Drainage area (A), in square miles, was determined from the most recent U.S. Geological Survey topographic maps.
- b. Mean basin elevation (E), in feet above mean sea level, was measured on 1:62,500 and 1:24,000 scale U.S. Geological Survey topographic maps for small drainage basins and on 1:250,000 scale U.S. Geological Survey maps for large basins. The elevation was computed by laying a grid over the map, determining the elevation at each grid intersection and averaging those elevations. The grid spacing was selected to give at least 20 intersections within the basin boundary.
- c. Mean annual runoff (R), in inches, was computed from the records of stream discharge at each gaging station. The isopleths of annual runoff shown on plate 1 were determined from these station data.
- d. Soils infiltration index (Si), in inches, was determined for sub-basins within the state by the Soil Conservation Service (written commun., 1970). These values are shown on plate 1. Weighted averages of these values were used for each gaged drainage basin.

These and other selected drainage basin characteristics have been tabulated for Missouri gaging stations by Skelton and Homyk (1970).

¹Equations are defined by data from streams with drainage areas of 0.2 to 42 square miles in the Plains and Plateaus. Data from 28 gaging stations were used to compute the equations.

²Standard error is defined as the standard deviation of the distribution (assumed normal) of residuals about the regression line and is a measure of the reliability of a regression. A standard error of 30 percent, for example, indicates that the flood-volume estimate obtained from the equation will be within [±]/₂ 30 percent of the correct value at about two-thirds of the ungaged sites.

DATA ARRANGEMENT

The streamflow data study by Skelton and Homyk (1970) indicated that a grouping of gaging stations by physiographic region and (or) drainage-area size is desirable to optimize results from regression analyses for many streamflow characteristics. Accordingly, regression runs using different groupings of the gaging-station data were made during the flood-volume study in order to compute the most stable regression equations with the lowest practical standard errors of estimate.

The three methods of data arrangement used for regression were as follows:

- a. All data were used in the regression to compute a single statewide equation for each flood-volume characteristic.
- b. Data were placed into one of two general groups according to physiographic location of gaging stations within the state (Plains or Plateaus).

c. Data were categorized according to drainage area size (less than 50 square miles and greater than 50 square miles).

Flood-volume data for the Southeastern Lowlands region were excluded from the regression runs for several reasons: (1) A network of only 14 continuous-record stations in the alluvial plain of Missouri and Arkansas did not provide sufficient data for a dependable regression analysis; (2) The terrain is so flat that delineation of contributing drainage areas is very difficult; and (3) Extensive and continuing man-made changes in the area are not conducive to effective regionalization of the available information.

The results of regression runs using the three methods of data arrangement plus a combination of methods "b" and "c" indicated that method "b" provided the optimum flood-volume equations for 1- to 30-day data based on stability of the regression coefficients and standard error size. These equations are presented in tables 2 and 3.

FLOOD-VOLUME CHARACTERISTICS FOR SMALL DRAINAGE AREAS

The continuous-record streamflow data available for analysis of flood-volume characteristics for streams with small drainage areas (less than 50 square miles) included 11 gaging stations in the Plains region and 17 in the Ozarks. The stations are well-distributed geographically and are hydrologically representative of small-area flood-volume characteristics in the two regions.

Regression runs were made to determine the feasibility of defining flood-volume equations for each region. However, the resulting regression equations showed considerable instability of the coefficients and uncertainty in the statistical significance of the independent variables.

Next, the data from all 28 Plains and Plateaus small-area stations were used in combination to compute flood-volume equations that would be applicable to both regions. The stability of the coefficients as well as the standard errors of the resulting equations showed substantial improvement over the previous regression runs, and the equations were considered satisfactory for use.

Table 4 is a summary of the regression results for 6-, 12- and 18-hour periods. The equations are applicable to ungaged sites in both the Plains and Plateaus.

ANALYSIS OF RESIDUAL ERRORS

For this report, residual errors are defined as the ratio of flood-volume data measured at each gaging station to that computed from the equations. The amount of deviation from an exact agreement between observed and computed values (1.00) and the geographic distribution or pattern of the values can be used to determine if some significant basin or climatic characteristic has been omitted from the

regional analysis. If so, a geographic correction factor can be applied to the appropriate equation.

Analysis of the residuals led to the conclusion that no significant regional patterns exist, although a few large deviations between observed and computed values were noted. Because of this random distribution pattern, no geographic correction factors were deemed necessary.

APPLYING STATION DATA AND REGIONAL EQUATIONS TO DESIGN PROBLEMS

When flood volume information may be used to solve hydrologic problems in the state, this report should be utilized in the following manner:

- a. Plate 1 should be examined to determine if any of the gaging station data presented in the appendix are applicable to the problem, with perhaps a small adjustment for drainage area differences. These data should be used whenever possible because they represent hydrologic experience at a particular site rather than a generalization of data from many other stations.
- b. At sites where data are not available, the regional equations of tables 2, 3, and 4 must be utilized

to obtain flood volume estimates. The equations of tables 2 and 3 are applicable to different physiographic regions; figure 1 must be used to choose the appropriate region. The independent variables necessary for solution of the equations are drainage area (A) in square miles, mean basin elevation (E) in thousands of feet, mean annual runoff (R) in inches, and soils infiltration index (Si) in inches. The variables A and E must be computed by the user from topographic maps. The variables R and Si may be obtained by locating the basin of interest on plate 1 and choosing the appropriate values. Use the center of the basin as the point of estimation for R and interpolate between the isopleths; use an areally weighted average for Si if more than one value is shown upstream from the point of interest.

LIMITATIONS OF REGIONAL EQUATIONS

Prior to project planning and analysis of structural design, the following limitations and restrictions applicable to the regional equations should be considered.

- a. The equations are applicable only to sites where flood flow is virtually natural. They do not apply to basins where high flows are affected by regulation, diversion, urbanization or channelization. Because of backwater effects, they are not applicable near the mouths of streams draining into larger streams.
- b. The equations should be used only within the range of the drainage-areas shown on tables 2,3 and 4.
- c. The equations are not applicable to the Southeastern Lowlands region.
- d. Regionalization results are less precise in the Ozarks than in the Plains region of the state. The cavernous limestone and dolomite formations of the area are capable of altering normal patterns of storm runoff and causing anomalous hydrologic situations within and among basins. The

major problem in generalizing flood volumes in the Ozarks is one of economics. Gross overdesign of structures is likely in those basins where significant amounts of storm runoff are diverted to natural underground flood-detention reservoirs and gradually released in the springs and seeps of the region. It can be assumed that only a few basins in the Ozarks are underlain by bedrock so cavernous as to cause a significant reduction in flood volumes during severe floods (recurrence interval of 10 years or more). Logan Creek basin in Reynolds County and the upper Eleven Point River basin in Howell and Oregon Counties are the only ones where sufficient data have been collected to verify this assumption, but a few others may exist. It is recommended that the areas of known deficient runoff patterns indicated on plate 1 be considered when flood-volume estimates are made for the Ozarks. If a structure is to be located in one of these areas, then field reconnaissance during a period of flood runoff will be necessary to make observations of significant deviations from normal flood runoff patterns. If deficient storm runoff is noted, adjustments to design estimates based on engineering judgment will be required to avoid gross overdesign.

a/ Recurrence interval is the average interval of time within which a given event will be exceeded once. Recurrence intervals are averages and do not imply regularity of occurrence; an event of 50-year recurrence interval might be

exceeded in consecutive years, for instance. In terms of probability, a 50-year flood volume has a 2-percent chance of occurring in any year.

<u>b/</u> Approximately.

FLOOD-VOLUME-DURATION RECURRENCE DATA (Continued).

a/ Recurrence interval is the average interval of time within which a given event will be exceeded once. Recurrence intervals are averages and do not imply regularity of occurrence; an event of 50-year recurrence interval might be

exceeded in consecutive years, for instance. In terms of probability, a 5-year flood volume has a 2-percent chance of occurring in any year. \underline{b} / Approximately.

FLOOD-VOLUME-DURATION RECURRENCE DATA (Continued).

a/ Recurrence interval is the average interval of time within which a given event will be exceeded once. Recurrence intervals are averages and do not imply regularity of occurrence; an event of 50-year recurrence interval might be

exceeded in consecutive years for instance. In terms of probability, a 50-year flood volume has a 2-percent chance of occurring in any year.
